## Abstract

In this paper we test for the hold-up problem by considering the effect of unions' bargaining power on the rate of growth of investment per worker and labour productivity across sectors characterised by different levels of sunk capital investments. We develop a search and matching model with heterogeneous sectors and ex-post collective wage bargaining and test the predictions of the model using a difference-in-difference approach on manufacturing sector data in a set of OECD countries during the period 1980-2005. We do find that union power slows down investment and labour productivity particularly in high sunk capital industries. We refine our empirical analysis showing that the underlying hold-up problem is exacerbated when strikes are not regulated after a collective contract is signed and there is no arbitration, while the concentration of unions and the presence of social pacts sustain cooperative equilibria and alleviate such a problem. Our results are robust to a series of controls and possible endogeneity of union power.

**Keywords:** Hold-Up, Unions, Sunk Investments, Search and Matching, Difference-in-Difference, Sectors.

We thank Fabiano Schivardi for comments and suggestions. We also thank seminar participants at III Workshop on "Institutions, Individual Behavior, and Economic Outcomes" in Argentiera, at the University of Hawaii and the University of Cagliari. Part of this work has been carried out while Sulis was visiting the Department of Economics at the University of Hawaii, thanks to that institution for its hospitality. The usual disclaimer applies.

# 1 Introduction

As the New York Times reports on January 2012: "[...] industry analysts had been skeptical of the combined potential of the two automakers since Fiat took control of Chrysler after it emerged from its government-sponsored bankruptcy [...] Once Fiat takes full ownership, the Chief Executive Officer Mr. Marchionne will be faced with the delicate decision of whether to locate its corporate headquarters in Italy, the United States or possibly a neutral location." Meanwhile, the NYT also notes: "Fiat said that it would withdraw from the leading employers' group in Italy as it pushed for more flexibility with its labor agreements, which the European Central Bank has deemed fundamental if Italy is to increase growth and pay down its crippling debt. The decision by Fiat, the country's largest manufacturer, comes a little more than a week after the employers' group, Confindustria, signed an agreement with labor unions that aimed to weaken national legislation that would liberalize the labor market by allowing employers to negotiate contracts with the workers at individual factories rather than be tied to national contracts. Mr. Marchionne [...] has threatened to pull all production out of Italy if Fiat is not allowed to override national contracts and negotiate directly with its workers."

While the specific case of the automobile industry in Italy discussed above can be of little interest for the wide audience of economists, the above example brings a series of general interesting questions that we want to answer in this paper: How relevant are contractual incompleteness and labour institutions for investment and productivity growth? Which are the channels through which such institutions influence these outcomes? Does the size of these effects depend on the degree of sunkness and/or the timing of investments by firms? In this paper we try to answer the above questions by focusing on the relation between sunk investments, unions' bargaining power and the underlying hold-up problem. In particular, we construct a search and matching model with sunk capital investments and ex-post collective wage negotiations to look at the effects of unions' bargaining power on the rate of growth of investment and labour productivity. We then put the model to data by evaluating the quantitative effect of coverage of union bargaining agreements on growth of investment per worker and hourly labour productivity across manufacturing sectors in a set of OECD countries during the period 1980-2005.

We show that higher union power has a relatively stronger negative effect on investment and productivity in sectors with a larger proportion of sunk physical capital. The reason rests on the classic concept of hold-up as analysed by Grout (1984): in a setting in which firms make their investment decisions before the wage negotiation takes place, a positive shock on unions' bargaining power increases the quasi-rents workers receive (via higher wages) without paying any capital cost; anticipating this, firms decide to invest less. In this paper, we further develop the basic intuition of Grout (1984) in a matching model with capital investment: in particular, we extend the model proposed by Acemoglu and Shimer (1999) by allowing for different sunk capital intensities across sectors. In our model, the degree of sunkness is captured by the amount of capital that firms cannot relet in case there is no production. A positive shock on the union's bargaining power lowers the rate of investment per worker and labour productivity relatively more in high sunk capital sectors. The intuition goes as follows: stronger union's bargaining power pushes unemployed workers to search for jobs in the sectors where the hold-up problem is more serious and wages are expected to be higher. Moreover, higher union power dampens vacancy creation in both sectors (because expected profits are lower), but less so in the one with a larger share of sunk capital, where the increase in job applications reduces the expected duration of a vacancy and the opportunity costs of idle capital equipment. In order to avoid that all unemployed workers stop applying for their jobs,

firms in the sectors with low sunk capital react by reducing capital investment less than the firms operating in sectors with a higher share of sunk capital.

We test the theoretical predictions of the model using different sources of data for growth of investment per worker and labour productivity in manufacturing sectors using a difference-in-difference approach as proposed by Rajan and Zingales (1998). In particular, we interact an indicator of union power at the country level (the coverage of union bargaining agreements) with a sectoral measure of sunk capital intensity (one minus the share of used capital investment in total capital investment at the industry level), as recently proposed by Balasubramanian and Sivadasan (2009) and derived from US industry data.

Our paper is associated to different strands of literature. It is related to the literature on the hold-up problem with relation-specific investments and contractual incompleteness in which under-investment occurs if contracts cannot be enforced (Williamson, 1985; Grossman and Hart, 1986; Hart and Moore, 1990).<sup>1</sup> In this context, Grout (1984) shows that, when there is rent sharing, irreversibility of capital investments and the structure of wage bargaining reduce investments. In fact, when long term contracts are not binding and capital investment is sunk, unions have the ex-post incentive to appropriate quasi-rents determining lower levels of investment.<sup>2</sup> This intuition is discussed with reference to the UK Trade Union Immunity Laws, which prevented firms from suing a trade union that ex-post breached a labour agreement thus generating losses for the firms. More recently, Card et al (2011) propose a two-period model showing that the hold-up problem is likely to be mitigated if there is a credible threat of liquidation by the firm in the second period. Using a matched employer-employee dataset for the manufacturing sector of the Veneto region in Italy, they test the empirical predictions of the model and find evidence that unions appropriate rents but after deducting the full cost of capital, suggesting that investment might be at its efficient level, even if the precision of their estimates do not allow them to exclude modest degrees of hold-up.<sup>3</sup>

Our paper is also referred to the studies on the cross-country effects of labour market regulations and institutions. In this setting, Fiori et al (2012) look at the effect of the interaction of labour and product market regulations on employment in OECD countries, and find that product market liberalisation is more beneficial when firing restrictions are higher, and that bargaining power of unions has negative employment effects. Using a sample of firms for a group of EU countries, Cingano et al (2010) show that employment protection legislation reduces investment per worker and value added per worker especially in high reallocation sec-

---

<sup>1</sup>General equilibrium effects of specificity are studied by Caballero and Hammour (1998), who analyse how the market system provides an inefficient solution to the unresolved microeconomic contracting problems. More recently, Acemoglu et al (2007) show that contractual incompleteness favours the adoption of less advanced technologies, and that the impact of contractual incompleteness tends to be stronger when there are important complementarities among the intermediate inputs, thus shaping the pattern of endogenous comparative advantage. Such intuition is empirically confirmed by Nunn (2007).

<sup>2</sup>Muthoo (1998) discusses the conditions that have to be fulfilled for investment levels to depend negatively on the degree of sunk costs. See also Che and Sakovics (2004) for a recent theoretical discussion of the hold-up problem.

<sup>3</sup>See Manning (1987) and Cavanaugh (1998) for early attempts to empirically evaluate the Grout effect. For papers that study the effects of unions on investment and productivity see Hirsch (1991) for the US, Morikawa (2010) for Japan, Addison et al (2007) for Germany, and Machin and Wadhvani (1991) for the UK among the others. See Metcalf (2003) for a cross country analysis of the effects of unions. See the papers by Doucouliagos and Laroche (2003a, 2003b) for meta-analyses on the relationship between unions and productivity and unions and tangible investments. See also Boeri et al (2001) for an exhaustive discussion of recent stylized facts and interpretations concerning the role of unions.

tors.<sup>4, 5</sup> Finally, our paper is also related to the literature on the relationship between unions' power, the structure of wage bargaining and macroeconomic outcomes (Cuckierman and Lippi, 1999).

The paper contributes to the literature in four main directions. First, we generalise the search and matching model of Acemoglu and Shimer (1999) by allowing for different extent of sunk capital across different sectors of the economy. In such a framework, we show that mobility of workers, by influencing vacancy creation and capital investment, is key to analyse the relative importance of the hold-up problem across different sectors. In second place, by using a difference-in-difference approach, we perform a direct test of the most important theoretical mechanism through which unions can negatively affect investment, namely the hold-up problem arising from the interplay between contractual incompleteness and sunk capital investments. Thirdly, ours is the first paper, to our knowledge, that investigates the effects of unions on productivity and investment in a cross country-cross industry comparison using a consistent source of data. Finally, we further explore the possibility that the relevance of the hold-up problem is influenced by features of the system of industrial relations and labour regulations that have somewhat been neglected in the previous literature, such as the concentration/fragmentation of unions, the possibility to go on strike after a contract has been signed, and the quality of labour relations.

Our empirical results imply a yearly investment growth differential over the period 1980-2000 of about 1.1% between a sector at the 75<sup>th</sup> percentile (*Transport equipment*) and at the 25<sup>th</sup> percentile of the sunk capital intensity distribution (*Leather products*) in a country at the 25<sup>th</sup> percentile of the union coverage distribution (such as the United Kingdom, with an average of 53.7%) compared to a country at the 75<sup>th</sup> percentile of union coverage (such as Spain, with an average of 83.6%). In the case of the growth rate of productivity growth, we find a growth differential of about 0.8%. We also find that an increase in union coverage during the period had a strong and negative effect on investment per worker. Moreover, our empirical results suggest that the negative effect of union coverage in sunk capital intensive sectors is stronger in countries in which regulation of strikes and arbitration are not legally binding, and in countries in which there is more fragmentation across unions. Finally, we show that, in countries in which there is a Social Pact between the government and the confederations of unions and employers (see Visser, 2011), the negative effect of unions on investment and productivity turns out to be not statistically significant.

We check the robustness of these results considering various different specifications. First, we consider the role of alternative determinants of industry growth by including the relevant interactions between industry and country characteristics, such as the average years of schooling at the country level and the sectoral human capital intensity, the country capital output ratio and the industry physical capital intensity, the sectoral measure of financial dependence and the country level of financial development. Second, we include interactions between sunk capital intensity and country level variables potentially correlated with union coverage such

---

<sup>4</sup>Cuñat and Melitz (2012) theoretically show that industry differences and labour market institutions can determine the pattern of comparative advantage: as a result, countries with more flexible labour markets tend to specialise in more dynamic industries. Conti and Sulis (2010) find that the negative effect of labour institutions as employment protection legislation on value added growth is stronger in more human capital intensive sectors.

<sup>5</sup>Using firm-level data on multinationals located in France, Bas and Carluccio (2010) show that multinational firms are more likely to import intermediate inputs from external independent suppliers instead from their own subsidiaries when importing from countries with empowered unions. Moreover, this effect is stronger for firms operating in capital-intensive industries.

as the change in union coverage over time, union density and its change over time, the level and coordination of wage bargaining, the coverage of unemployment benefits, the extent of employment protection legislation, the presence of barriers to foreign direct investments and the rule of law. Third, we examine whether our interaction between union coverage and sunk capital intensity partly captures other interactions of unions with industry features that might be correlated with sunk capital intensity, such as R&D intensity and physical capital intensity. Fourth, we control for possible endogeneity of union power by instrumenting it with political economy variables. We conclude that our robustness checks confirm the baseline results.

The rest of the paper is organized as follows. In section 2 we develop the theoretical model and derive the main empirical implications we test in the data. In sections 3 and 4 we present the data and the estimation method, while in section 5 we discuss our results. Section 6 concludes.

## 2 The Model

### 2.1 Production and Matching Technology

We consider a continuous-time model with a continuum of infinitely-lived and risk-neutral workers with perfect foresight and common discount rate  $r$ . The economy is composed by one final consumption good  $Y$ , whose price is normalised to 1, and two intermediate goods. The final good production function takes a CES form:

$$Y = \left[ Y_a^{\frac{\sigma-1}{\sigma}} + Y_b^{\frac{\sigma-1}{\sigma}} \right]^{\frac{\sigma}{\sigma-1}}. \quad (1)$$

in which  $Y_a$  ( $Y_b$ ) is the amount of the intermediate good  $a$  ( $b$ ) used in the production process of the final good while  $\sigma > 1$  allows for a situation in which one of the intermediate goods is equal to zero. Perfect competition is assumed in all, both intermediate and final, good markets; therefore cost minimisation in the final good sector leads to the following inverse demand function for each intermediate good:

$$p(Y_i) \equiv \frac{dY}{dY_i} = \left( \frac{Y_i}{Y} \right)^{-\frac{1}{\sigma}}; \text{ for } i \in \{a, b\}. \quad (2)$$

Following the standard search and matching framework (Pissarides, 2000), we assume that, in each intermediate sector, a firm is composed of a single (filled or vacant) job. Firms in sector  $i$  have to choose an amount of equipment  $k_i$  before meeting the workers. The unit price of capital is assumed fixed and equal to  $p$ : the latter has to be paid at any instant in time by a firm, either with a vacancy open or with a filled job. Our assumption of a rental price of capital is different from the one made by Acemoglu and Shimer (1999) who assume that the firm buys up-front the total amount of capital; by way of contrast, in our case, the firm is allowed to relet at least a share  $\gamma_i$  for  $i \in \{a, b\}$  of it. An hold-up problem arises because firms must choose and pay the amount of capital  $k_i$  before the wage negotiation takes place.

The labour force is normalised to 1. There are frictions in the labour market. In any intermediate sector  $i \in \{a, b\}$ , a matching function yields the measure of matches for certain values of unemployed people searching for a job in that sector,  $u_i$ , and vacancies  $v_i$ :  $m_i = m(v_i, u_i)$ . The function  $m(., .)$  has constant returns to scale and it is increasing and concave in each argument. Labour market tightness in sector  $i$  is defined as  $\theta_i \equiv v_i/u_i$ , for  $i \in \{a, b\}$ . A vacancy is filled according to a Poisson process with rate  $q(\theta_i) \equiv m_i/v_i$ ,  $q'(\theta_i) < 0$ . A

job-seeker moves into employment at rate  $\theta_i \cdot q(\theta_i) \equiv m_i/u_i$ , increasing in  $\theta_i$ .<sup>6</sup> Following most of the literature, we consider a Cobb-Douglas technology for the matching function:  $m_i = u_i^{1-\eta} v_i^\eta$ ; however, our results still apply to more general functional forms. At a certain exogenous rate  $s$ , the capital investment  $k_i$  attached to either a vacancy or a filled job breaks down: in that case, the worker becomes unemployed. We also assume that unemployed workers are able to direct their search towards either sector and a non-arbitrage condition discussed below ensures that there is no expected gain in choosing either option. Therefore, if  $\lambda$  denotes the endogenous share of unemployed workers searching for a job in sector  $a$ , we have the following laws of motion of unemployment in the two sectors:

$$\dot{u}_a = s \cdot e_a - \theta_a q(\theta_a) \cdot \lambda u \quad (3)$$

$$\dot{u}_b = s \cdot e_b - \theta_b q(\theta_b) \cdot (1 - \lambda) u \quad (4)$$

in which  $e_a$ ,  $e_b$  and  $u$  denote the level of employment in sector  $a$ , in sector  $b$  and the total number of unemployed people in the economy, respectively. Using  $1 = e_a + e_b + u$ , we can derive the level of employment in both sectors at the steady state:

$$e_a = \frac{\lambda \theta_a q(\theta_a)}{s + \lambda \theta_a q(\theta_a) + (1 - \lambda) \theta_b q(\theta_b)} \quad (5)$$

$$e_b = \frac{(1 - \lambda) \theta_b q(\theta_b)}{s + \lambda \theta_a q(\theta_a) + (1 - \lambda) \theta_b q(\theta_b)} \quad (6)$$

In sector  $i = \{a, b\}$ , each worker produces  $y_i$  units of the intermediate good via a technology  $y_i = f(k_i) = k_i^\alpha$ . Therefore, using  $Y_i = y_i \cdot e_i$  and equations (5) and (6), the inverse demand (2) can be re-written in steady state as:

$$p(Y_a) = \left\{ 1 + \left[ \frac{1 - \lambda}{\lambda} \left( \frac{k_b}{k_a} \right)^\alpha \cdot \frac{\theta_b q(\theta_b)}{\theta_a q(\theta_a)} \right]^{\frac{\sigma-1}{\sigma}} \right\}^{\frac{1}{\sigma-1}} \quad (7)$$

$$p(Y_b) = \left\{ 1 + \left[ \frac{\lambda}{1 - \lambda} \left( \frac{k_a}{k_b} \right)^\alpha \cdot \frac{\theta_a q(\theta_a)}{\theta_b q(\theta_b)} \right]^{\frac{\sigma-1}{\sigma}} \right\}^{\frac{1}{\sigma-1}} \quad (8)$$

Because of diminishing marginal productivity, the price of the good  $i$  negatively depends on the fraction of unemployed workers searching for a job in sector  $i$ .

## 2.2 Investment Decision and Free-Entry Condition

The expected discounted value of a filled job verifies the following Bellman equation:

$$r \Pi_i^E = p(Y_i) \cdot k_i^\alpha - w(k_i) - p \cdot k_i - s \Pi_i^E + \dot{\Pi}_i^E \quad (9)$$

for  $i = \{a, b\}$ , where the last term on the RHS measures the appreciation of  $\Pi_i^E(k)$ . The equation above says that the firm's revenues are equal to the amount of the intermediate good produced (multiplied by its price  $p(Y_i)$ ) net of the real wage  $w(k_i)$  and the rental cost of equipment that the firm must pay as long as the capital is not destroyed,  $p \cdot k_i$ ; in the latter

<sup>6</sup>Moreover, it is assumed that  $\lim_{\theta_i \rightarrow 0} q(\theta_i) = +\infty$ ,  $\lim_{\theta_i \rightarrow +\infty} q(\theta_i) = 0$ ,  $\lim_{\theta_i \rightarrow 0} \theta_i q(\theta_i) = 0$ , and  $\lim_{\theta_i \rightarrow +\infty} \theta_i q(\theta_i) = +\infty$ .

case, the firm exits the market. The expected discounted value of a firm with a job vacancy reads as:

$$r\Pi_i^V = \max_{k_i} -\gamma_i p \cdot k_i + q(\theta_i) [\Pi_i^E - \Pi_i^V] - s\Pi_i^V + \dot{\Pi}_i^V \quad (10)$$

for  $i = \{a, b\}$ : the firm's problem is to choose the optimal level of capital that maximizes  $r\Pi_i^V$ . It is important to note that when the vacancy is idle the capital equipment is not used in the production process: however, we assume that there is a fraction  $1 - \gamma_i$  of the equipment that firms are able to relet or dispose in other ways in order to cover its cost. As a result,  $\gamma_i p \cdot k_i$  is the flow cost of capital paid by firms that are searching for a worker: in this sense, the parameter  $\gamma_i$  measures the extent of sunkness of capital. In order to single out more starkly the impact of irreversible investment in our model, we impose  $\gamma_a > \gamma_b$  as the only technological difference between the two sectors. As Acemoglu and Shimer (1999), we restrict the firms to choose the same level of capital for any job in each sector.

Using equations (9) and (10), we get the following F.O.C.:

$$\frac{q(\theta_i)}{r + s + q(\theta_i)} [p(Y_i)\alpha \cdot k_i^{\alpha-1} - w'(k_i) - (1 - \gamma_i)p] = \gamma_i p \quad (11)$$

for  $i \in \{a, b\}$ . At the equilibrium, the marginal cost of capital - the RHS of (11) - must be equal to its marginal revenue - the LHS of (11).

There is free-entry of vacancies: in particular, firms enter the labour market as long as expected profits are nonnegative:  $\Pi_i^V = 0$ . Following Pissarides (1985), we also impose that the level of vacancies instantaneously changes in order to ensure that the condition  $\Pi_i^V = 0$  always holds, both in and out of the steady-state equilibrium. In this case,  $\dot{\Pi}_i^V = 0$  and equation (10) becomes:

$$\Pi_i^E = \frac{\gamma_i p \cdot k_i}{q(\theta_i)} \quad \text{for } i \in \{a, b\}. \quad (12)$$

Then, rearranging equations (9) and (10) yields:

$$\frac{p(Y_i)k_i^\alpha - w(k_i) - (1 - \gamma_i)p k_i + \dot{\Pi}_i^E}{r + s + q(\theta_i)} = \frac{\gamma_i p \cdot k_i}{q(\theta_i)} \quad \text{for } i \in \{a, b\}. \quad (13)$$

Equation (13) says that the expected cost of filling a vacancy is equal to the expected revenues obtained from a job. Notice that the parameter  $\gamma_i$  has a twofold effect on the zero profit condition. On the one hand, it raises the expected cost of a vacancy, as the latter is increasing in the rental cost of capital in case of no production, i.e.  $\gamma_i p$ . On the other hand, it also raises the expected revenues for a vacancy, because the capital gain for filling a vacancy is greater the larger the fraction of sunk capital.

## 2.3 Workers' Preferences and Wage Bargaining

The expected discounted utilities of an employed and an unemployed worker in sector  $i \in \{a, b\}$ , are, respectively:

$$rJ_i^E = w(k_i) + s [J_i^U - J_i^E] + \dot{J}_i^E, \quad (14)$$

$$rJ_i^U = \theta_i q(\theta_i) [J_i^E - J_i^U] + \dot{J}_i^U. \quad (15)$$

The interpretation of these Bellman equations is standard. Being employed (respectively, unemployed) is equivalent to holding an asset that yields an instantaneous utility equal to the

wage  $w(k_i)$  (respectively zero, as we assume for simplicity that there are neither unemployment benefits nor home production in this economy) and the capital gain in case the worker becomes unemployed (respectively gets a job) multiplied by the corresponding entry rate. Finally,  $J_i^E$  and  $J_i^U$  are the appreciation terms.

Since unemployed workers are free to search for either a job in sector  $a$  or a job in sector  $b$ , a non-arbitrage condition must ensure that the expected utility of being unemployed is the same across sectors:<sup>7</sup>

$$rJ_a^U - J_a^U = rJ_b^U - J_b^U. \quad (16)$$

In order to solve the model, we need to impose a wage rule: as our main interest is the effect of union power on investment and productivity, we do not consider the individual bargaining process that is common in standard search and matching models (see Pissarides, 2000); we instead consider a collective bargaining process where, in each sector, unions and firms' representatives negotiate over the wage.

To model unions' preferences, we consider an utilitarian case. In particular, firms in sector  $i$  have an utility equal to  $e_i \cdot \Pi_i^E$ , i.e. the expected revenues of each single firm multiplied by the number of firms with a filled job in the market.<sup>8</sup> Moreover, there is a union which cares about the sum of the utilities of its members. For simplicity, we also assume that the workers' union represents all the workforce in that sector: therefore, the utility of the union when bargaining in sector  $i$  is equal to  $e_i \cdot J_i^E + u_i \cdot J^U$ , for  $i \in \{a, b\}$ .

Wages are determined by bilateral generalised axiomatic Nash bargaining that takes the following form:

$$w(k_i) = \operatorname{argmax} [e_i \cdot J_i^E + u_i \cdot J^U - (e_i + u_i) \cdot J^U]^\beta \cdot [e_i \cdot (\Pi_i^E - \Pi_i^V)]^{1-\beta}$$

for  $i \in \{a, b\}$ . At the equilibrium, the negotiation always ends up in an agreement. The F.O.C. of the above problem is:

$$\beta \cdot (\Pi_i^E - \Pi_i^V) = (1 - \beta) \cdot (J_i^E - J^U) \quad \text{for } i \in \{a, b\}. \quad (17)$$

Using the Bellman equations for workers and firms (9), (10), (14) and (15), the F.O.C. of the bargaining problem yields:

$$\beta [p(Y_i)k_i^\alpha - w(k_i) - p k_i] = (1 - \beta) [w(k_i) - rJ^U + J^U] \quad (18)$$

for  $i \in \{a, b\}$ .<sup>9</sup> Rearranging, we get:

$$p(Y_i)k_i^\alpha - w(k_i) = (1 - \beta) [p(Y_i)k_i^\alpha - rJ^U + J^U] + \beta \cdot p \cdot k_i \quad (19)$$

for  $i \in \{a, b\}$ . Differentiating this equation with respect to  $k_i$  and plugging it into (11) yields:

$$\mathbb{G}_i(\theta_i, \theta_j, \lambda, k_i, k_j) \equiv (1 - \beta)p(Y_i) \cdot \alpha k_i^{\alpha-1} - p \frac{(r + s)\gamma_i + q(\theta_i)(1 - \beta)}{q(\theta_i)} = 0 \quad (20)$$

for  $i, j \in \{a, b\}$ ,  $i \neq j$ . The implicit function  $\mathbb{G}_i(\theta_i, \theta_j, \lambda, k_i, k_j) = 0$  represents the firm's optimal choice of capital in sector  $i$  when the wage is determined by bilateral bargaining.

<sup>7</sup>Since the expected utility  $J^U$  is invariant across sectors, we will suppress the subscript  $i$  henceforth.

<sup>8</sup>Felbermayr et al. (2008) and Bauer and Lingens (2010) have recently used the same approach.

<sup>9</sup>Note that  $\beta \cdot [\Pi_i^E - \Pi_i^V] = (1 - \beta) \cdot [J_i^E - J^U]$ .

Notice that the endogenous variables  $\theta_j$ ,  $\lambda$ , and  $k_j$  appear in equation (20) because the price of the intermediate good  $p(Y_i)$  depends on them (see equations (2), (3) and (4)). The first term in  $\mathbb{G}_i(\theta_i, \theta_j, \lambda, k_i, k_j) = 0$  is the marginal gain of investment which is decreasing in  $k_i$  because the production function has diminishing returns on capital. The second term is the marginal cost of investment which is increasing in  $\theta_i$  as a higher labour market tightness raises the expected duration of filling a vacancy, which in turn implies more time with an idle equipment. In equilibrium, marginal costs must be equal to marginal benefits, so an increase in  $\theta_i$  must be accompanied by a lower  $k_i$ . Notice also that the higher the fraction of sunk capital  $\gamma_i$ , the higher the marginal cost of investment.

Using the free entry condition (12), the Bellman equations for unemployed workers (15), and the Nash sharing rule (17), the non-arbitrage condition (16) takes the following form:

$$rJ^U - \dot{J}^U = \beta \cdot p \cdot \theta_a \cdot \gamma_a \cdot k_a = \beta \cdot p \cdot \theta_b \cdot \gamma_b \cdot k_b. \quad (21)$$

Rearranging we get:

$$\frac{k_b}{k_a} = \frac{\theta_a \cdot \gamma_a}{\theta_b \cdot \gamma_b}. \quad (22)$$

Equation (21) allows us to express the wage equation below without the terms  $J^U$  and  $\dot{J}^U$ :

$$w(k_i) = \beta \cdot [p(Y_i) \cdot k_i^\alpha + p \cdot k_i (\gamma_i \cdot \theta_i - 1)] \quad \text{for } i \in \{a, b\} \quad (23)$$

The expression in (23) is similar to the wage equation obtained in search and matching models with individual bargaining and no sunk capital. Workers receive a fraction  $\beta$  of the revenues earned by the intermediate firms plus an amount that positively depends on labour market tightness. Notice also that the wage equation is increasing in  $\gamma_i$ : the larger the extent of sunk capital in the production function (i.e. the closer is  $\gamma_i$  to 1), the bigger the hold-up problem faced by firms, as they have a greater fraction of capital that cannot be employed for alternative uses when production does not occur (i.e., before the matching with the worker and in case of wage disagreement). In other words, a higher share of sunk capital weakens the firms' bargaining position and, as a result, the bargained wage tends to be higher.

Thanks to equation (23) the non-arbitrage condition (22) can also be easily interpreted. In fact, it simply states that one sector cannot jointly combine a bigger share of sunk capital  $\gamma_i$ , a higher level of equipment  $k_i$ , and a tighter labour market compared to the other sector. This is because this would imply both a higher real wage (via equation 23) and a lower expected duration in unemployment, which in turn would entail that no worker would search for a job in the other sector. Therefore, in equilibrium, the product of these three variables must be equal across sectors.

We can substitute the RHS of (23) into (13) and rewrite the free entry zero profit condition as:

$$\frac{(1 - \beta)p(Y_i)k_i^\alpha + \dot{\Pi}_i^E}{[(r + s)\gamma_i + q(\theta_i)(1 - \beta + \beta\gamma_i\theta_i)]} = \frac{p \cdot k_i}{q(\theta_i)} \quad (24)$$

for  $i \in \{a, b\}$ . Notice that, after taking the wage equation into account, the effect of  $\gamma_i$  on the expected profits is negative. Therefore a higher share of sunk capital entails a lower rate of vacancy creation. The increase in the wage bill and in the expected costs of a vacancy, that a higher share of sunk capital entails, outweighs the positive "capital gain" effect on revenue present in equation (13).

Figure 1: Equilibrium

## 2.4 Existence and Uniqueness of the Steady-State Equilibrium

Before turning to the dynamics of the model, we look for the conditions that ensure the existence and uniqueness of a steady-state equilibrium. It is straightforward to notice that if there exist steady-state equilibrium values for  $k_i$ ,  $\lambda$  and  $\theta_i$ , for  $i \in \{a, b\}$ , then all the other remaining variables of the model ( $e_i$ ,  $u$ ,  $w(k_i)$ , and the expected discounted utilities of the agents) are also uniquely determined. We proceed by dividing equation (20) by equation (24) evaluated at the steady-state (i.e. with  $\dot{\Pi}_i^E = 0$ ). We get:

$$\mathbb{W}(\theta_i) \equiv \frac{1}{\alpha} - 1 - \frac{\beta \cdot \gamma_i \theta_i q(\theta_i)}{(r+s)\gamma_i + q(\theta_i)(1-\beta)} = 0 \quad (25)$$

for  $i \in \{a, b\}$ . The implicit function  $\mathbb{W}(\theta_i) = 0$  uniquely determines the equilibrium value of  $\theta_i$  for  $i \in \{a, b\}$ .

Using the non-arbitrage condition (22), we can write  $k_a$  in terms of  $k_b$  and plug the resulting expression into the equations  $\mathbb{G}_i(\theta_i, \theta_j, \lambda, k_i, k_j) = 0$ ,  $i, j \in \{a, b\}, i \neq j$ . Then, we end up with a system with two equations,  $\mathbb{G}_a = 0$  and  $\mathbb{G}_b = 0$ , for two unknowns,  $k_b$  and  $\lambda$ . Using the Inada conditions for the job flows rates and the implicit function theorem, it is easy to show that the system admits only one solution in  $k_b$  and  $\lambda$ .<sup>10</sup> Once  $k_b$  and  $\lambda$  are determined, the equilibrium values of employment  $e_a$  and  $e_b$  are uniquely obtained by the flow equations in (5) and (6) evaluated at the steady-state. Figure (1) intuitively shows that an equilibrium exists and it is unique.

## 2.5 Labour Unions and Sunk Capital

The purpose of our paper is to determine the impact of unions' bargaining power on sectors that, for some technological reason, differ in terms of the amount of sunk capital used in their

<sup>10</sup>Computations are in Appendix A.

production function. In terms of our model, this amounts to study the dynamics of the growth rate of investment per worker and the average productivity of labour both in sector  $a$  and in sector  $b$  following a positive shock on  $\beta$ , the parameter that represents the bargaining power of unions.

In particular, we consider the two equations of motion of unemployment (3) and (4), the zero profit conditions (12) and (24), the optimal choice of capital (20) and the non-arbitrage condition (22) that contain the unknowns  $e_i$ ,  $\Pi_i^E$ ,  $\theta_i$ ,  $k_i$ , and  $\lambda$  for  $i \in \{a, b\}$ . We express (3), (4), (12), (20) and (22) as functions of the unknowns  $e_i$ ,  $\Pi_i^E$ ,  $\theta_i$ ,  $k_i$ , and  $\lambda$ , respectively, and plug the resulting expressions in equation (24).<sup>11</sup> After some algebra, equation (24) takes the form of a nonlinear autonomous differential equation in  $\theta_i$  and  $\theta_j$ :  $\dot{\theta}_i = h_i(\theta_i, \theta_j)$  for  $i, j \in \{a, b\}, i \neq j$ . Computing the Jacobian matrix of the system  $\dot{\theta}_a = h_a(\theta_a, \theta_b), \dot{\theta}_b = h_b(\theta_b, \theta_a)$  and the corresponding eigenvalues we get that the unique equilibrium is an unstable node (computations are in Appendix B). This is a common result in search and matching models (see Pissarides, 2000): if the system is not at its steady-state value, it diverges to an explosive path. Moreover, for the implicit function  $\mathbb{G}_i(\theta_i, \theta_j, \lambda, k_i, k_j) = 0$ , the capital per worker  $k_i$  also has the same behaviour for  $i \in \{a, b\}$ . So, when a positive shock to  $\beta$  hits the economy,  $k_i$  will adjust immediately to its new steady-state value.

Hence for the purposes of this paper, to study the growth rate of investment (productivity), we just need to compare the "new" steady state value with the "old" one. Proposition below illustrates the results:

**Proposition 1** *If and only if  $\beta > \eta$ , a positive shock on the bargaining power of unions  $\beta$  lowers both the growth rate of investment and the growth rate of average labour productivity. The decrease is more pronounced in sector  $a$ , that has a higher fraction of sunk capital,  $\gamma_a$ .*

**Proof.** We need to prove that

$$0 > \frac{dk_b}{d\beta} \frac{1}{k_b} > \frac{dk_a}{d\beta} \frac{1}{k_a}. \quad (26)$$

Totally differentiating the system composed by  $\mathbb{G}_a(\theta_a, \theta_b, \lambda, k_a, k_b) = 0$ ,  $\mathbb{G}_b(\theta_b, \theta_a, \lambda, k_b, k_a) = 0$ ,  $\mathbb{W}_a(\theta_a) = 0$ ,  $\mathbb{W}_b(\theta_b) = 0$  and the non-arbitrage condition (22), and applying the implicit function theorem we get that  $\frac{dk_b}{d\beta} < 0$  iff  $\beta > \eta$ . Computations are in Appendix B. Then, instead of computing the same derivative for  $k_a$ , notice that

$$\frac{d\frac{k_b}{k_a}}{d\beta} = \frac{k_b}{k_a} \cdot \left( \frac{dk_b}{d\beta} \frac{1}{k_b} - \frac{dk_a}{d\beta} \frac{1}{k_a} \right). \quad (27)$$

So  $\frac{d\frac{k_b}{k_a}}{d\beta} > 0$  is a necessary and sufficient condition to prove that both inequalities in (26) are verified. Using the non arbitrage condition in (22), we get:

$$\frac{d\frac{k_b}{k_a}}{d\beta} = \frac{\gamma_a \gamma_b \left( \frac{d\theta_a}{d\beta} \theta_b - \frac{d\theta_b}{d\beta} \theta_a \right)}{(\theta_b \cdot \gamma_b)^2}. \quad (28)$$

Differentiating  $\mathbb{W}_i(\theta_i) = 0$  and applying the implicit function theorem, we get:

$$\left. \frac{d\theta_i}{d\beta} \right|_{\mathbb{W}_i=0} = -\frac{\theta_i}{\beta} \frac{\gamma_i(r+s) + q(\theta_i)}{(1-\eta)\gamma_i(r+s) + (1-\beta)q(\theta_i)} \quad \text{for } i \in \{a, b\}. \quad (29)$$

<sup>11</sup>See Appendix B.

Substituting this expression into equation (28) yields:

$$\frac{d\frac{k_b}{k_a}}{d\beta} = \frac{\theta_a \theta_b \beta^{-1} [\gamma_a q(\theta_b) - \gamma_b q(\theta_a)] (r+s)(\beta-\eta)}{[(1-\eta)\gamma_a(r+s) + (1-\beta)q(\theta_a)] [(1-\eta)\gamma_b(r+s) + (1-\beta)q(\theta_b)]}.$$

Using  $\mathbb{W}_a(\theta_a) = 0$  and  $\mathbb{W}_b(\theta_b) = 0$ , it is easy to show that  $\gamma_a q(\theta_b) > \gamma_b q(\theta_a)$ .<sup>12</sup> Hence we conclude that  $\frac{d\frac{k_b}{k_a}}{d\beta} > 0 \Leftrightarrow \beta > \eta$ . Using equation (27), this means that

$$0 > \frac{dk_b}{d\beta} \frac{1}{k_b} > \frac{dk_a}{d\beta} \frac{1}{k_a} \Leftrightarrow \beta > \eta. \quad (30)$$

The decrease in the rate of investment is more pronounced in the sector with a larger share of sunk capital  $\gamma_a > \gamma_b$ . The average productivity of labour is equal to  $k_i^\alpha$  for  $i \in \{a, b\}$ .<sup>13</sup> So we have:

$$\frac{dk_i^\alpha}{d\beta} \frac{1}{k_i^\alpha} = \alpha \frac{dk_i}{d\beta} \frac{1}{k_i},$$

therefore, results in (30) show that even the change in average labour productivity is bigger in absolute value in the sector with a higher fraction of sunk capital. ■

The interpretation of Proposition 1 goes as follows. First, notice that an increase in union's bargaining power reduces labour market tightness  $\theta_i$  (see  $\mathbb{W}_i(\theta_i) = 0$ ) relatively more in the sector with a lower share of sunk capital.<sup>14</sup> A higher  $\beta$  has a negative effect on firms' revenues in both sectors, but it also pushes unemployed workers to search for a job in the sector with more sunk capital, as the wage gains stemming from the hold-up problem are increasing with union's bargaining power.<sup>15</sup> This shift of the unemployed workers mitigates the negative effect of higher  $\beta$  in the sector with a larger share of sunk capital because it reduces the expected costs of filling a vacancy in that sector. Therefore vacancy creation, and in turn labour market tightness, decreases less in the high sunk capital sector than in the other sector. Finally, for the non arbitrage condition (22), one sector cannot experience a larger reduction in both capital and tightness compared to the other. In fact, this would imply lower wages and a smaller probability of finding a job: as a consequence, all unemployed workers would stop searching for a job in that sector. Therefore the sector with a higher share of sunk capital, which is characterised by a smaller decrease in tightness, also displays a larger reduction in the rate of investment per worker.

## 3 Data

### 3.1 Country-Industry Level

We use two different sources of data for our two dependent variables, the growth rate of investment per worker and the growth rate of hourly labour productivity. The first source is the "Trade, Production and Protection, 1976-2004" database by Nicita and Olarreaga (2007) originally based on the UNIDO database (UNIDO henceforth). From this data, we extract investment (gross fixed capital formation) per worker as our main dependent variable for a set of 11 OECD countries: Australia, Austria, Belgium, Finland, Greece, Italy, Japan, South

<sup>12</sup>Details are available upon request from the authors.

<sup>13</sup>Recall that in each intermediate sector  $Y_i = k_i^\alpha \cdot e_i$

<sup>14</sup>This can be seen by differentiating equation (29) with respect to  $\gamma_i$ .

<sup>15</sup>In the limit case in which  $\beta = 0$  the wage is the same across sectors.

Korea, Portugal, Spain and the United Kingdom. In the UNIDO database, the sectoral level of aggregation is the ISIC Rev2 classification with 28 manufacturing sectors, and for most countries information is available for the entire period 1980-2000.<sup>16</sup>

As in the UNIDO dataset monetary variables are in current prices, we had to use EUKLEMS country-sector deflators to obtain such variables at constant prices. In the case of gross fixed capital formation, for most countries we recover such information at a level of sectoral aggregation of 13 manufacturing sectors.<sup>17</sup> If not available, we obtain data on gross investment deflators from the OECD's STAN database (Austria and Belgium) or national sources (Greece, Portugal and South Korea). Finally, when information was not available at all, we use averages for other countries. Finally, we also face a problem linked to currency conversions. As original data are expressed in US dollars, we also decided to take into account purchasing power parities: we convert back the currency units into national currencies and then apply PPPs conversion factors to eliminate price variations.

The second source of data is the public release of the EUKLEMS database which contains detailed information on various industry-level variables for a larger set of OECD countries for the period 1980-2005 (see Inklaar et al., 2008). We extract information on hourly labour productivity (which is not available in the UNIDO database) for 23 manufacturing sectors according to the ISIC Rev3.1 classification for 17 countries: Australia, Austria, Belgium, Denmark, Finland, France, Germany, Greece, Ireland, Italy, Japan, the Netherlands, Portugal, South Korea, Spain, Sweden, and the United Kingdom.<sup>18</sup> We drop other EU and non-EU countries as data were not available for the complete covered period and the US, as the latter is used as the benchmark in our differences-in-differences approach.<sup>19</sup>

For some countries we do not have information on investment and productivity for all sectors, but in no case the number of sectors falls below 20 (out of 28) and 17 (out of 23) in the UNIDO and EUKLEMS dataset respectively. Our regressions are based on 266 and 347 observations which correspond to more than 85% of potential observations in both datasets. We report descriptive statistics for sectoral growth of investment per worker and hourly labour productivity in the first columns of Tables 1 and 2.

## 3.2 Industry Level

Our measure of sunk capital intensity at the industry level is derived from Balasubramanian and Sivadasan (2009), and it is only available for the US manufacturing sector. They define an index of capital resalability as the share of used capital investment in total capital investment outlays at the 4 digits SIC87 aggregate level for the years 1987 and 1992. The proposed index is a valid measure of physical capital resalability based on the supposition that in industries where capital expenditure is not firm-specific (and there is an active secondary market for physical capital) it is likely that used capital would account for a relatively higher share of

---

<sup>16</sup>The time span covered by the UNIDO database does not allow us to include other OECD countries. We also checked investment data in the OECD STAN database, but the latter was either incomplete or had a higher level of aggregation than the UNIDO one.

<sup>17</sup>In principle, if one works with first differences (e.g. growth of investment), this should not matter because in our empirical specification we have country and sector fixed effects. Still, we decided to deflate the data to allow for more precision in our estimates.

<sup>18</sup>We also extracted information for labour productivity, calculated as value added divided by the number of employees in the UNIDO database. We have only used the latter to verify the robustness of our estimates: results are available upon request.

<sup>19</sup>As the data for value added are in current prices, we use price deflators available in the EUKLEMS dataset. When not directly available, we use averages for the other countries over the same years.

total investment. Thus, they expect their capital resalability index to be an inverse measure of the degree of sunkness of investment across industries.

In Tables 1 and 2, we report for the UNIDO and EUKLEMS datasets respectively, the main descriptive statistics for our measure of sunk capital intensity (which is an average of the 1987 and 1992 values reported in Balasubramanian and Sivadasan, 2009), where the latter is obtained after applying appropriate procedures for aggregation of data and conversion of sectors using different classification systems (see the Data Appendix for details). We also report descriptives for some additional sector level control variables derived from US data that do not vary across countries in our sample: physical capital, external financial dependence, human capital and R&D intensity. As a measure of human capital/skill intensity we use the measure proposed by Ciccone and Papaioannou (2009) and subsequently used in Conti and Sulis (2010).<sup>20</sup> Physical capital intensity is computed as the ratio between real gross capital stock and value added in the US in 1980 using data taken from the EUKLEMS. Our measure of R&D intensity is proxied by the R&D expenditure to value added ratio in the US in 1990 using data taken from the OECD ANBERD database. Finally, our measure of external financial dependence for 1980 is directly derived from Rajan and Zingales (1998).

### 3.3 Country Level

The main country level variables are reported in Table 3 as averages for the period 1980-2005.<sup>21</sup> Our measure of union power is adjusted coverage of bargaining union agreements, as proposed by Visser (2011). It is calculated as the number of employees covered by wage bargaining agreements as a proportion of all wage and salary earners in employment with the right to bargaining, expressed as percentage, adjusted for the possibility that some sectors or occupations are excluded from the right to bargain. Such indicator is the standard measure of union power and it is preferable to union density for a variety of reasons (see Checchi and Lucifora, 2002). The latter is calculated as net union membership as a proportion of wage and salary earners in employment and it is a measure of the demand for union representation that we use as a robustness check of our specification. As inspection of Table 3 shows, union coverage is persistently higher than union density and it ranges from around 11% in Korea to about 97% in Austria. In Europe, Scandinavian countries traditionally show both very high union density and coverage (higher than 70% and 80%, respectively), while Mediterranean countries have quite high excess coverage (difference between coverage and density, e.g., Spain has 84% and 14% respectively); finally Anglo-Saxon countries have less unionised labour markets.<sup>22</sup>

As mentioned above, in our study we also include a set of variables that should capture some relevant aspects of the industrial relations system. The first is taken from Visser (2011) and it is a summary measure of concentration/fragmentation of unions. In particular, it is the effective number of confederations, defined as the inverse of the Herfindahl index appropriately discounted to take into account the weight of smaller confederations: the index gives an idea of the (inverse) degree of concentration at the central or peak level in a given country. The

---

<sup>20</sup>We calculate average years of schooling for each educational attainment in 1970. Then, for each sector, we calculate the share of employees in each educational attainment level and multiply this share by the average years of schooling calculated above.

<sup>21</sup>Note that the UNIDO and EUKLEMS datasets cover a slightly different period of time (1980-2000 and 1980-2005, respectively); hence average measures of such variables can slightly differ across datasets. In both cases we use appropriate country level measures, but for space reason we just report relevant information for the period 1980-2005.

<sup>22</sup>For the US, union density is equal to 15%, while union coverage is 18%.

second, taken from Mueller and Philippon (2011), is a measure of the quality of labour relations that ranges from hostile to productive ones as reported by direct interviews with managers of firms in different countries.

Finally, we use a set of indicators that reflect some aspects of labour legislation and are directly related to collective disputes, union behaviour and involvement of unions and employers in government decisions on social and economic policy. Four of them are from Botero et al (2004). The first is a dummy variable that equals one if a strike is not illegal even if there is a collective agreement in force, and zero otherwise; the second equals one if there is no mandatory waiting period or notification requirement before strikes can occur, and zero otherwise; the third equals one if labour laws do not make conciliation procedures or other alternative-dispute-resolution mechanisms (other than binding arbitration) mandatory before a strike, and zero otherwise; the fourth equals one for countries where parties to a labour dispute are not required by law to seek third party arbitration or the government is not always entitled to impose compulsory arbitration on them, and equals zero otherwise.<sup>23</sup> The fifth (see Visser, 2011) equals one if there is a Social Pact, defined as “publicly announced formal policy contracts between the government and social partners over income, labour market or welfare policies that identify explicitly policy issues and targets, means to achieve them, and tasks and responsibilities of the signatories.”

We refer to the Appendix for a description of other country level variables that we use in the empirical analysis.

## 4 Estimation Method

Our empirical framework is based on the difference-in-difference approach pioneered by Rajan and Zingales (1998) and subsequently employed in many other empirical applications (see Nunn, 2007). In order to evaluate whether unions’ power tends to reduce the growth of investment per worker and labour productivity particularly in sunk capital intensive industries, we estimate different versions of the following baseline equation:

$$\Delta \ln y_{s,c,1980\_2000} = \alpha(Sunk_s * Union_{c,1980\_2000}) + \gamma W'_s Z_c + \delta \ln y_{s,c,1980} + v_s + u_c + \varepsilon_{s,c} \quad (31)$$

where the dependent variable  $y$  is the average growth rate of investment per worker (labour productivity) in country  $c$  and sector  $s$  over the period 1980-2000 (1980-2005);  $v_s$ ,  $u_c$  and  $\varepsilon_{s,c}$  are sector and country specific fixed effects and a conventional error term, respectively;  $Sunk_s$  is the sunkness intensity of each industry derived from US data;  $Union_c$  defines different indicators of average union power at the country level over the period 1980-2005.

A negative sign for the coefficient  $\alpha$  of the interaction term  $Sunk_s * Union_c$  would indicate that countries in which unions are stronger tend to have slower growth of investment per worker and labour productivity, especially in industries with higher sunk costs. In other words, union power tends to slow down the growth of labour productivity and investment per worker disproportionately in sunk capital intensive industries.

In equation (31) we take into account possible convergence effects by including in all regression specifications the log of the dependent variable at the beginning of the period. Moreover, country fixed effects should control for the effects of any omitted variable at the

---

<sup>23</sup>As explained in Botero et al (2004), the term "compulsory arbitration" refers to a law that imposes arbitration of private disputes even against the will of the parties. It may influence workers bargaining power in two ways, namely by granting them an alternative to costly strikes in case of deadlocks in the negotiation process, but it may also limit their right to strike.

country level, such as the quality of institutions, macroeconomic conditions over the period, social norms, etc.; in turn, industry dummies may capture differences in technologies or sector specific patterns of growth. Furthermore, our regression specification takes into account other possible determinants of industry productivity and investment growth by including the relevant country and sector interactions  $W'_s Z_c$ , such as the country years of schooling and the sector human capital intensity in 1980; the country capital-output ratio and the sectoral physical capital intensity in 1980 and the industry dependence on external finance and the country level of financial development. The inclusion of  $W'_s Z_c$  is important because there is evidence that countries with an abundant factor tend to specialise in industries that use intensively that factor. Controlling for the relevant country-industry interactions should allow us to take into account the possibility that  $W_s$  (e.g. the industry physical capital intensity) and  $Sunk_s$  or  $Z_c$  (e.g. the country capital stock, level of financial development, etc.) and  $Union_c$  are correlated: in this case, the omission of the relevant country-industry interactions would tend to bias the OLS estimates of  $\alpha$ . In addition to this, there might be other country-level variables, potentially correlated with  $Union_c$ , that might interact with industry sunk capital intensity: hence, as a robustness check, in some regression specifications we also include additional interactions between  $Sunk_s$  and country level variables such as financial development, human capital, employment protection legislation, other labour market institutions, rule of law, etc.

Finally, in order to consider the possibility that union behaviour might interact with some other industry characteristics, in some specifications we augment our regressions with interactions between  $Union_c$  and sector level variables, such as R&D, human and physical capital intensity as well as industry dependence on external finance. Furthermore, given that there might be reasons to believe that causality might go in the other direction, namely from growth to union power (see below), we also estimate a version of equation (31) in which we instrument  $Union_c$  with variables related to the political history of each country.

## 5 Results

### 5.1 Baseline Results

In Tables 4 and 6 we start testing the main implication of our model, namely that the growth rates of investment per worker and labour productivity are reduced particularly in high sunk cost industries in countries where labour unions have strong bargaining power, the latter mainly proxied by the average percentage of employees covered by wage bargaining agreements over the sample period.

In column 1 of both Tables we start with a parsimonious specification of equation (31), as we only control for the initial level of investment per worker (labour productivity) in 1980 as well as for both country and industry fixed effects. As we can see, the coefficient of the interaction between the industry degree of sunkness and union coverage is negative and strongly statistically significant in both regressions. In particular, the coefficient of -0.00791 in Table 4 implies a yearly investment growth differential of about 1.1% between a sector at the 75<sup>th</sup> percentile (*Transport equipment*) and at the 25<sup>th</sup> percentile of the sunk capital intensity distribution (*Leather products*) in a country at the 25<sup>th</sup> percentile of the union coverage distribution (such as the United Kingdom, with an average of 53.7% over the period 1980-2000) compared to a country at the 75<sup>th</sup> percentile of union coverage (such as Spain, with an average of 83.6%). In the case of the growth rate of labour productivity, the coefficient reported in column 1 of Table 6 suggests a yearly growth differential of about 0.8% between two sectors at the 75<sup>th</sup> and

25<sup>th</sup> percentile of the sunk capital intensity distribution in a country at the 25<sup>th</sup> percentile of the union coverage distribution compared to a country at the 75<sup>th</sup> percentile of union coverage.

In column 2 of Tables 4 and 6 we start assessing the robustness of this result by including the relevant country-industry interactions contained in the matrix  $W'_s Z_c$  discussed in the previous Section and commonly employed in cross country-industry growth regressions: we can see that the interaction between sunk intensity and union coverage remains negative and statistically significant. In column 3 we start adding country level variables that might be plausibly thought to affect investment per worker or labour productivity growth particularly in high sunk cost industries. First, we consider the role played by union density given that it has often been treated as an alternative to union coverage as a proxy for the bargaining power of unions: as we can see, the interaction term is very small and largely insignificant in both Tables, while the sunk intensity-union coverage interaction is remarkably stable.<sup>24</sup> In column 4 we add interactions of *Sunk* with both a variable capturing the level (firm, industry or country) at which bargaining takes place and the degree of wage coordination, which however turn out to be largely statistically insignificant. In column 5 we add the interactions of *Sunk* with an indicator of coverage of unemployment benefits and with an OECD index of employment protection legislation of both regular and temporary workers: these two variables capture sources of workers bargaining power that do not depend, at least directly, on the strength of the trade unions, the first because it affects the fall back position of workers in the bargaining process by raising their outside option, and the latter because it tends to insulate incumbent workers by raising labour adjustment costs (Fiori et al, 2012). Empirical results suggest that these two interactions are positive in both regressions, but that only the one involving EPL is statistically significant in the labour productivity regression. There might be different explanations for this result: perhaps a more rigid labour market might tend to incentivise firms to invest in on the job training particularly in high sunk cost industries, given the likely relatively more limited scope in these industries to substitute capital for labour.<sup>25</sup>

Finally, in columns 6 and 7 we add interactions of *Sunk* with an indicator of barriers to foreign direct investments in the manufacturing sector and an indicator of the rule of law.<sup>26</sup> While the interaction between *Sunk* and barriers to FDI is not statistically significant in both regressions, there is some evidence that countries with a stronger rule of law tend to have a higher growth rate of investment per worker in high sunk cost industries, probably reflecting the fact that a stronger rule of law might be associated to higher government commitment power not to use taxation to expropriate investors of the quasi rents generated by sunk investments.<sup>27</sup>

In Table 5 and 7 we consider different extensions as well as additional robustness checks to our baseline regression. In column 1 we address possible endogeneity concerns of union coverage: first, there can be some country level omitted variables for which we have not controlled for that might tend to affect the growth rates of labour productivity and investment per worker especially in high sunk costs industries; alternatively, it might be argued that growth and union

---

<sup>24</sup>However if we drop the sunk-union coverage interaction in our baseline specification, the interaction of sunk and union density is negative and statistically significant.

<sup>25</sup>Some mild favorable empirical evidence for this pattern of the capital labour elasticity of substitution can be found in Oberfeld and Raval (2012). See also Belot et al (2004).

<sup>26</sup>Countries with strong unions might have stronger incentives to attract foreign direct investments, as recently argued by Haufler and Mittermaier (2011).

<sup>27</sup>We have also separately included interaction of *Sunk* with the country human capital level, the capital to output ratio, the level of financial development and the country average unemployment rate over the period, and results were virtually unaltered. Regression results have been omitted for reasons of space.

coverage are jointly determined if countries that tend to specialise in industries characterised by both slow growth in investment per worker and by a high fraction of sunk capital are also more likely to have stronger unions and, in particular, high coverage rates. In column 1 of both Tables we report the result of an IV regression otherwise identical to that reported as column 2 of Tables 4 and 6 where we have instrumented union coverage with a dummy equal to one for countries that had experienced a right-wing dictatorship spell before 1980 and zero otherwise, and with the average fraction of votes held by left wing parties at the government over the 1980-2000 period.<sup>28</sup> The rationale for these two instruments is that right-wing dictatorships might have fought the development of the labour unions movement while, in turn, a strong presence of left wing parties in the governments might have favoured the growth of labour unions (Fiori et al, 2012). The first stage regression, whose results are available from the authors upon request, confirms our expectations and suggests that our instruments are not weak and pass the Sargan test of instrument validity.<sup>29</sup> The second stage regression displayed in column 1 of Tables 5 and 7 confirm that higher union coverage rates slow down growth in investment per worker and labour productivity particularly in sunk intensive industries, although the magnitude of the effect is reduced with respect to OLS estimates.

In column 2 we add an interaction between a country's union coverage rate and the industry R&D intensity, as the latter is weakly correlated with the degree of sunkness at industry level in our sample and because there is empirical evidence suggesting both that R&D intensive industries tend to be more volatile and that some labour market institutions tend to depress growth in volatile industries (Cuñat and Melitz, 2012). For these reasons, we believe it is important to check that the negative interaction between *Sunk* and union coverage is not simply capturing the negative effect of union coverage on investment rates and productivity growth in R&D intensive industries. Empirical results displayed in column 2 do not confirm that this is the case, as the sunk-union coverage interaction is always negative and statistically significant; in turn, the R&D-union coverage interaction is negative but statistically significant only in the investment regression.

In column 3 we include an interaction between the union coverage rate and the industry physical capital intensity: controlling for this interaction is very important not only because the latter is positively correlated with the industry degree of sunkness, but because our theoretical model predicts that it is the sunk nature of capital investments to generate the hold-up problem, and not physical capital intensity per se. As the empirical results show, the union coverage-physical capital intensity interaction is never significant and the magnitude of the sunk intensity-union coverage interaction is barely altered.<sup>30</sup>

So far we have measured union coverage as the average value over the entire sample period: however, it might be argued that the variation of union coverage might not be exogenous, as it

---

<sup>28</sup>The countries that experienced a dictatorship spell are Italy, Germany, Austria, Japan, Korea, Greece, Portugal and Spain.

<sup>29</sup>The Kleibergen-Paap test statistics are 55.5 and 44.2 in the investment per worker and labour productivity regressions, respectively; in turn, the Sargan test statistics are 0.75 (p value 0.102) and 1.9 (p value 0.16), respectively.

<sup>30</sup>It is possible to argue (Baldwin, 1983) that firms in high sunk cost industries might tend to increase debt as a sort of commitment device to be tough against unions. If this results in structurally higher dependence towards external finance in high sunk cost industries, then it might be important to control for an interaction between union coverage and an industry financial dependence. When we do so, the interaction of union coverage with the degree of industry sunkness remains negative and statistically significant. Finally, we have also run a regression where we have controlled for an interaction between union coverage with an industry's human capital intensity without affecting our main results. Results are available from the authors upon request.

could be driven also by other country-industry developments over the period: for this reason, we have proxied union's bargaining power with the value taken by union coverage as of 1980. Econometric results displayed in column 4 confirm our baseline results and therefore suggest that measuring union coverage as either the mean or the beginning of the period value does not matter much.<sup>31</sup>

In column 5 we have considered the possibility that it is not the level of union coverage per se to be important, but its change over the period: empirical results suggest that countries that experienced a larger increase in union coverage over the sample period had both a lower growth of investment per worker and labour productivity in high sunk cost industries, although the effect is estimated with noise in Table 7. In column 6 we repeat the same exercise with the change in union density (but omitting union coverage), given the large changes that occurred during our sample period in the latter variable in many countries: results again suggest that countries where union density increased more over the period might have experienced a reduction in both labour productivity and investment per worker growth rates, although only in the latter case the effect is estimated with precision.

In column 7 we have added an interaction between *Sunk* and the degree of fragmentation of confederations of unions (see Data section above): in this case, we expect that in countries where union membership is not concentrated, unions that are in charge of negotiations will try to fully exploit their bargaining power because the chances to be replaced by other unions in the future are higher than in countries with a very concentrated union membership; as a result, the possibility of sustaining cooperative equilibria between firms and unions is expected to be lower. We find confirmation for this prediction in the data: in fact, empirical results suggest that countries where union membership is very fragmented tend to have a significantly lower investment growth in sectors characterised by a relatively higher share of sunk capital, while in the case of the productivity regression the coefficient of the interaction is highly insignificant.<sup>32</sup>

Finally, in column 8 we have interacted *Sunk* with a variable measuring the quality of the labour relations (Mueller and Philippon, 2011): the intuition for including this control is that in countries characterised by good labour relationships, the existence of high union coverage rates might not affect investments and labour productivity. However, when we control for the quality of labour relations (see the Data section) we do not find confirmation of this effect, as the interaction between labour relations and *Sunk* is positive as expected (which means that countries with "bad" labour relations tend to display lower investment and productivity growth in sunk intensive industries) but also statistically insignificant at conventional levels of confidence; in turn, the sunk-union coverage interaction is always negative, statistically significant and with barely altered coefficients.

## 5.2 Refinements

So far we have presented empirical evidence showing that union bargaining power tends to reduce the growth rates of investment per worker and labour productivity particularly in industries characterised by a relatively large fraction of sunk capital stock, as predicted by our theoretical model. However, it might be of some interest to assess whether the magnitude

---

<sup>31</sup>It is important to note that proxying union bargaining power with the beginning of the period union coverage does not alter none of our main results.

<sup>32</sup>We also run our baseline regressions splitting the sample into different groups of countries, depending on whether the fragmentation index was above or below the median. Both for investment and labour productivity growth regressions, we find that the negative effect of union coverage in sunk industries is much stronger in the case of countries with more fragmented union confederations. Results are available upon request.

of this effect varies with some regulations that characterise the labour relations system across countries such as those we previously discussed in Section 3.3. For instance, in some countries the government has the power to impose compulsory arbitration among parties involved in a labour dispute, or at least there exist mandatory conciliation procedures before a strike can occur; in turn, in some countries it is forbidden for unions to strike if there is a collective agreement in place, or there is a waiting or notification period before a strike can take place. For this reason, using information contained in Botero et al. (2004), we have run a series of baseline regressions (corresponding to column 2 of Tables 4 and 6) splitting the sample across some of the country-level dimensions of labour relations we have just mentioned. Before turning to the discussion of empirical results for the growth rate of investment per worker, it is however important to acknowledge that some regressions are based on few observations and therefore we should view these results as suggestive only.<sup>33</sup>

In Table 8 we have split the sample according to the existence (column 2) or not (column 1) of a law that allows strikes when a collective agreement has been already signed.<sup>34</sup> The existence of such a regulation is important because one could expect that, if the law is in place, the hold-up problem should be significantly alleviated, because the possibility for unions to behave opportunistically might be significantly reduced. This is exactly what we find, as the effect of union coverage is about halved for the group of countries characterised by regulations that forbid strikes when a collective agreement is in place.<sup>35</sup> Then we have split the sample according to whether there is (column 4) or not (column 3) in the country a mandatory waiting period before a strike can take place.<sup>36</sup> Econometric results show that higher union coverage tends to significantly slow down the growth of investment per worker particularly in high sunk capital industries for both country groups, but the magnitude of the effect seems to be notably smaller in countries where a notification or waiting period before a strike can occur is compulsory. In subsequent columns countries have instead been split according to whether there is (column 6) or not (column 5) a mandatory conciliation procedure: empirical results suggest that, in both country groups, union coverage negatively affect the growth of investment per worker, but that the magnitude is three times larger in countries where there is not a mandatory conciliation procedure.<sup>37</sup> In columns 7 and 8 the sample has been instead split according to whether in the country there is (column 8) or not (column 7) a mandatory arbitration procedure and we find that the negative impact of union coverage is higher in countries where there is no mandatory arbitration, while for countries where there is a compulsory and binding arbitration, the negative impact of union coverage is marginally statistically insignificant.<sup>38</sup>

Finally, we have considered, for each country, whether, for the majority of years included in our sample period, both unions and employers had been routinely involved in government

---

<sup>33</sup>Moreover, we do not explore the issue of why some regulations are in place in some countries but not in others. Qualitatively the results for labour productivity growth are very similar with one exception that we will discuss later. Results are available from the authors upon request.

<sup>34</sup>The countries in our sample where such regulation is not in place are the UK, France, Italy and the Netherlands.

<sup>35</sup>In the case of the labour productivity growth regression we do not see any notable difference in the magnitude of the effect between the two groups of countries.

<sup>36</sup>The countries where there was a mandatory waiting period were Canada, Denmark, Spain, Finland, Greece, Korea, Netherlands, Portugal and Sweden.

<sup>37</sup>Countries with mandatory conciliation procedures were Australia, Denmark, Spain, Finland, Korea, Netherlands

<sup>38</sup>Countries with mandatory arbitration procedures were Australia, Spain and Korea.

decisions concerning social or economic policy issues (i.e., Social Pacts; see Visser, 2011).<sup>39</sup> In this case, our idea is that the government, by involving (always, or at least irregularly) unions and employers in economic policy decisions, creates a more cooperative framework between the parts and favors the sustainability of a cooperative equilibrium characterised by unions that refrain from exploiting their bargaining power. Our empirical results provide some favourable evidence for this hypothesis, as we see that only in countries characterised by the absence of concertation higher coverage ratios are associated to slower growth in investment per worker in sunk capital intensive industries.

## 6 Concluding Remarks

In this paper, we test for the hold-up problem by considering the effect of union power on investment and productivity across sectors with different levels of sunk capital investments. We develop a search and matching model with sunk capital investments and ex-post collective wage bargaining and test the predictions of the model by considering the effects of unions' bargaining power on the rate of growth of investment per worker and hourly labour productivity. We use different sources of data on manufacturing sectors in two sets of partially overlapping OECD countries during the period 1980-2005.

Using a difference-in-difference approach, we verify that union power reduces growth of investment per worker and labour productivity in industries with higher proportions of sunk physical capital. This result is robust to a series of sensitivity checks. First, we have controlled for other determinants of industry growth by means of interactions between a country factor abundance and an industry factor intensity. Second, we include interactions between sunk capital intensity and country level variables potentially correlated with union coverage such as the change in union coverage over time, union density and its change over time, the level and coordination of wage bargaining, the coverage of unemployment benefits, the extent of employment protection legislation, the presence of barriers to foreign direct investments and the rule of law. Third, we examine whether our interaction between union coverage and sunk capital intensity partly captures other interactions of unions with industry features that might be correlated with sunk capital intensity, such as R&D and physical capital intensity. Finally, we have taken into account possible endogeneity concerns of union behaviour.

We refine our analysis using a set of indicators that reflect some aspects of industrial relations and that are directly related to collective disputes, union behaviour and involvement of unions and employers in government decisions on social and economic policy. In particular, we find that the effects of union power on investment and productivity is stronger when in a country there is the possibility of strikes even if there is a collective agreement in force, when there is no mandatory waiting period, there are no other alternative conciliation procedures or possibility of seeking third party arbitration. On the other hand, the effect of unions is less relevant when cooperative equilibria are sustainable: this happens when there is less fragmentation of union representation and when social pacts, by involving unions and employers in economic policy decisions, are in force.

Overall, our results suggest that the contractual incompleteness in labour relations and the resulting hold-up problem are a relevant phenomenon that might have sizeable effects on the growth of investment and labour productivity. On the other hand, there is some evidence that the system of industrial relations, by influencing the degree of contractual incompleteness,

---

<sup>39</sup>The countries where firms and unions were involved in economic policy decisions were Austria, Belgium, Canada, Germany, Denmark, Finland, Netherland, Portugal and Sweden.

might play a role in determining the magnitude of the problem. However, at least two issues remain to be investigated: first, why some countries persist in adopting labour regulations that exacerbate the hold up problem; second, how the type of contractual incompleteness analysed here drives the pattern of comparative advantage.

# Appendices

## A. Existence of Equilibrium

The equations  $\mathbb{G}_i(\theta_i, \theta_j, \lambda, k_i, k_j) = 0$ ,  $\mathbb{W}(\theta_i) = 0$  for  $i \in \{a, b\}$ , and (22) compose a system in five unknowns:  $\theta_a$ ,  $\theta_b$ ,  $k_a$ ,  $k_b$ , and  $\lambda$ . It is easy to check that there exists a unique  $\theta_i$  that solves the equation  $\mathbb{W}(\theta_i) = 0$  for  $i \in \{a, b\}$ . This is because  $\frac{d\mathbb{W}(\theta_i)}{d\theta_i} < 0$  and the last term in the LHS of such equation goes to 0 (resp.  $-\infty$ ), as  $\theta_i$  goes to 0 (resp.  $+\infty$ ) for the Inada conditions for the job filling rate.

From the non-arbitrage condition (22), we have  $k_a = k_b \cdot \frac{\gamma_b \theta_b}{\gamma_a \theta_a}$ . Using the RHS of equation and  $\mathbb{W}(\theta_i) = 0$ , the implicit functions  $\mathbb{G}_a(\theta_a, \theta_b, \lambda, k_a, k_b) = 0$  and  $\mathbb{G}_b(\theta_b, \theta_a, \lambda, k_b, k_a) = 0$  respectively become:

$$\begin{aligned} p(Y_a) \cdot k_b^{\alpha-1} &= \frac{p \beta \gamma_a \theta_a}{(1-\alpha)(1-\beta)a} \cdot \left( \frac{\theta_a \gamma_a}{\theta_b \gamma_b} \right)^{1-\alpha} \\ p(Y_b) \cdot k_b^{\alpha-1} &= \frac{p \beta \gamma_b \theta_b}{(1-\alpha)(1-\beta)a} \end{aligned} \quad (32)$$

in which

$$\begin{aligned} p(Y_a) &= \left\{ 1 + \left[ \frac{1-\lambda}{\lambda} \left( \frac{\theta_a \gamma_a}{\theta_b \gamma_b} \right)^\alpha \cdot \frac{\theta_b q(\theta_b)}{\theta_a q(\theta_a)} \right]^{\frac{\sigma-1}{\sigma}} \right\}^{\frac{1}{\sigma-1}} \\ p(Y_b) &= \left\{ 1 + \left[ \frac{\lambda}{1-\lambda} \left( \frac{\theta_b \gamma_b}{\theta_a \gamma_a} \right)^\alpha \cdot \frac{\theta_a q(\theta_a)}{\theta_b q(\theta_b)} \right]^{\frac{\sigma-1}{\sigma}} \right\}^{\frac{1}{\sigma-1}} \end{aligned} \quad (33)$$

Notice that  $\frac{d\mathbb{G}_a}{d\lambda} < 0$  and  $\frac{d\mathbb{G}_a}{dk_b} < 0$ . So  $\mathbb{G}_a = 0$  describes a decreasing relationship in the  $(k_b, \lambda)$  space. In addition, the Inada conditions for the job filling rate and the concavity of the production function imply that  $k_b \rightarrow +\infty$  as  $\lambda \rightarrow 0$  and  $k_b$  tends to a positive finite number when  $\lambda \rightarrow 1$ .

As far as it concerns  $\mathbb{G}_b = 0$ ,  $\frac{d\mathbb{G}_b}{d\lambda} > 0$  and  $\frac{d\mathbb{G}_b}{dk_b} < 0$ . So  $\mathbb{G}_b = 0$  describes an increasing relationship in the  $(k_b, \lambda)$  space. In addition as  $\lambda \rightarrow 1$ ,  $k_b \rightarrow +\infty$  and as  $\lambda \rightarrow 0$ ,  $k_b$  tends to a positive finite number. Figure 1 intuitively shows that an equilibrium in  $\lambda$  and  $k_b$  exists and is unique. Once  $k_b$  is determined, we get the steady-state value of  $k_a$  via the non-arbitrage condition (22). All the remaining variables of the model ( $e_i$ ,  $u_i$ , and the expected discounted values for workers and firms) are obtained by using the steady-state values of  $\theta_a$ ,  $\theta_b$ ,  $k_a$ ,  $k_b$ , and  $\lambda$ .

## B. Dynamics of the System and Comparative Statics

### B1. Dynamics of the System

We first express (24) as a first-order non linear differential equation in  $\theta_i$ . To do so, rearranging eqs. (2), (5) and (6) we have

$$\frac{p(Y_a)}{p(Y_b)} = \left( \frac{Y_a}{Y_b} \right)^{-\frac{1}{\sigma}} = \left( \frac{\lambda \theta_a q(\theta_a)}{(1-\lambda) \theta_b q(\theta_b)} \right)^{-\frac{1}{\sigma}}$$

If we divide the first equation in (32) by the second one, we can get an explicit solution for  $(1 - \lambda)/\lambda$  (conditional on  $\theta_i$  that is determined by  $\mathbb{W}(\theta_i) = 0$ , for  $i \in \{a, b\}$ ):

$$\frac{1 - \lambda}{\lambda} = \left( \frac{\gamma_a}{\gamma_b} \right)^{\alpha \cdot \sigma} \cdot \left( \frac{\theta_a}{\theta_b} \right)^{1 - \eta + \alpha \cdot \sigma} \quad (34)$$

Plugging the RHS of (34) into the first equation in (32) allows us to have an equation in which  $k_b$  depends on  $\theta_a$  and  $\theta_b$  only:

$$k_b^{\alpha-1} \cdot \left[ \left( \frac{\theta_a \gamma_a}{\theta_b \gamma_b} \right)^{-\alpha(\sigma-1)} + \left( \frac{\theta_a \gamma_a}{\theta_b \gamma_b} \right)^{\frac{\alpha(\sigma-1)}{\sigma}} \right]^{\frac{1}{\sigma-1}} - \frac{p \theta_b \gamma_b}{(1-\alpha)} \frac{\beta}{1-\beta} = 0 \quad (35)$$

From the (22), we also get:

$$k_a^{\alpha-1} \cdot \left[ \left( \frac{\theta_a \gamma_a}{\theta_b \gamma_b} \right)^{1-\sigma} + \left( \frac{\theta_a \gamma_a}{\theta_b \gamma_b} \right)^{\frac{\sigma-\alpha(\sigma+1)}{\sigma}(1-\sigma)} \right]^{\frac{1}{\sigma-1}} - \frac{p \theta_b \gamma_b}{(1-\alpha)} \frac{\beta}{1-\beta} = 0 \quad (36)$$

Differentiating (12), we also get:

$$\dot{\Pi}_i^E = \gamma_i \left[ \frac{d k_i}{d \theta_i} \cdot \frac{1}{q(\theta_i)} - k_i \frac{q'(\theta_i)}{q^2(\theta_i)} \right] \dot{\theta}_i \quad \text{with } i \in \{a, b\} \quad (37)$$

Plugging (35), (36), and (37) into (24) and using  $\mathbb{G}_i = 0$  with  $i \in \{a, b\}$ , we get:

$$\begin{aligned} \dot{\theta}_a &= \frac{\theta_a}{\gamma_a} \cdot \frac{-\frac{1-\alpha}{\alpha} [(r+s)\gamma_a + q(\theta_a)(1-\beta)] + \beta \theta_a q(\theta_a) \gamma_a}{\frac{\tau_a}{\alpha-1} + \eta} \\ \dot{\theta}_b &= \frac{\theta_b}{\gamma_b} \cdot \frac{-\frac{1-\alpha}{\alpha} [(r+s)\gamma_b + q(\theta_b)(1-\beta)] + \beta \theta_b q(\theta_b) \gamma_b}{\frac{1+\alpha\tau_b}{\alpha-1} + \eta} \end{aligned} \quad (38)$$

in which  $\tau_a$  and  $\tau_b$  are both functions of  $\theta_a$  and  $\theta_b$  and are lower than zero. Notice that the unique equilibrium of the system is hyperbolic. After linearising the system in (38) around the steady state, it is easy to see that both eigenvalues of the Jacobian matrix are positive, and therefore the steady state is an unstable node.

## B2. Comparative Statics

We want to prove that  $\frac{dk_b}{d\beta} < 0$ . For the concavity of the production function, it is sufficient to prove that the LHS of (36) is decreasing in  $\beta$ . After some algebra we get:

$$\frac{dk_b}{d\beta} < 0 \iff \frac{p}{(1-\alpha)} \frac{\theta_b \gamma_b}{1-\beta} \cdot \frac{(r+s)(\beta-\eta)}{(1-\eta)\gamma_b(r+s) + (1-\beta)q(\theta_b)} \times \left[ \frac{\alpha \cdot \epsilon \cdot (\gamma_a q(\theta_b) - \gamma_b q(\theta_a))}{(1-\eta)\gamma_a(r+s) + (1-\beta)q(\theta_a)} - \frac{\gamma_b}{1-\beta} \right] < 0$$

where

$$\epsilon \equiv \frac{\frac{1}{\sigma} \left( \frac{\theta_a \gamma_a}{\theta_b \gamma_b} \right)^{\frac{\alpha(\sigma-1)}{\sigma}} - \left( \frac{\theta_a \gamma_a}{\theta_b \gamma_b} \right)^{-\alpha(\sigma-1)}}{\left( \frac{\theta_a \gamma_a}{\theta_b \gamma_b} \right)^{\frac{\alpha(\sigma-1)}{\sigma}} + \left( \frac{\theta_a \gamma_a}{\theta_b \gamma_b} \right)^{-\alpha(\sigma-1)}} < 1 \text{ because } \frac{\theta_a \gamma_a}{\theta_b \gamma_b} > 1.$$

After some further computations the term inside the square brackets can be rewritten as:

$$\frac{\alpha \cdot \epsilon \cdot (1 - \beta)q(\theta_b)(\gamma_a - \gamma_b)}{(1 - \eta)\gamma_b(r + s) + (1 - \beta)q(\theta_b)q(\theta_b)} \cdot [(1 - \eta)\gamma_b(r + s) + (1 - \eta)(1 - \beta)q(\theta_b)] + \\ - \gamma_b [(1 - \eta)\gamma_a(r + s) + (1 - \beta)q(\theta_a)] < 0.$$

The inequality is verified because  $\gamma_a > \gamma_b$ ,  $q(\theta_b) < q(\theta_a)$  and the first term on the LHS is smaller than 1. Then it is easy to see that  $\beta > \eta$  is a necessary and sufficient condition for  $\frac{dk_b}{d\beta} < 0$ .

## C. Data Appendix

### C1. Conversion of Sectors and Weights

Although detailed information and appropriate routines are available upon request, in this subsection we provide a sketch of the procedures for aggregation of data and conversion of sectors using different classification systems. Our measure of sunk capital from Balasubramanian and Sivadasan (2009) is available at the SIC1987 – 4 digits level (459 industries) for the years 1987 and 1992, while data for investment per worker and labour productivity are available at the ISIC Rev2 – 3 digits level (28 industries) and ISIC Rev3.1 – 2 digits level (23 industries), respectively. Hence, we first aggregate the sunk capital index at the 2 and 3 digits level of the SIC87 classification by using 1987 and 1992 yearly shares of value added obtained from the 2005 release of the NBER-CES Manufacturing Industry Database by Bartelsman and Gray (1996). Then, following Balasubramanian and Sivadasan (2009), for each sector we calculate an average between the index in 1987 and 1992.

To convert the sunkness measure to the ISIC Rev2 – 3 digits level (28 industries) we aggregate SIC87 at 3 digit level (143 industries) and use routines provided by Haveman and available at his homepage.<sup>40</sup> To obtain our sunkness measure at the ISIC Rev3.1 – 2 digits level we use the SIC87 at 2 digit level (20 industries) that gives almost a perfect match between the two sources of data. However, as the latter has a lower number of sectors, we use the 3 digit classification when necessary. Using this procedure, we are not able to match only one sector (Recycling). Finally, depending on different classification systems, we use similar procedures for the other industry level variables mentioned above and reported in Tables 1 and 2, i.e., physical capital intensity, external financial dependence, human capital intensity and R&D intensity.

### C2. Other Country Level Variables

Other labour market variables that are directly correlated with union presence are also included in our analysis. We first consider an index of coordination of wage bargaining taken from Visser (2011) that "ranges from economy-wide bargaining, based on enforceable agreements between the central organizations of unions and employers affecting the entire economy or entire private sector, or on government imposition of a wage schedule, freeze, or ceiling (level 5), to industry bargaining with no or irregular pattern setting, limited involvement of central organizations, and limited freedoms for company bargaining (level 3) to fragmented bargaining, mostly at company level (measure 1)." From the same source, we also include the level of bargaining,

<sup>40</sup>See <http://www.maclester.edu/research/economics/page/haveman/Trade.Resources/tradeconcordances.html#FromusSIC>

which takes values between 5 (i.e. economy wide bargaining) and 1 (fragmented bargaining, mostly at the company level).

Other labour market institutions that are strictly correlated with union presence are the coverage of unemployment benefits and employment protection legislation. We derive a measure of coverage of unemployment benefits from the FRDB database on labour market institutions (see Aleksynska and Schindler, 2011), the latter is calculated as the number of individuals who, at a given point in time, receive UI benefits relative to the number of unemployed. We use, as a measure of EPL, the recent OECD indicator EP\_v1, which is an unweighted average of employment protection for regular and temporary contracts, and we construct an average measure for the period 1985-2005. As there is a strong link between labour and product market regulation, we also include a measure of barriers to foreign direct investments taken from the OECD. A measure for the rule of law has been proxied with the structure and security of property rights index reported in the Economic Freedom of the World database.

Finally, we also include in our set of controls standard macroeconomic variables that should influence growth of investment and labour productivity as the physical capital to output ratio, the schooling level of the population aged 15 or more and the level of financial development. These variables come from conventional sources: financial development is measured as the ratio between domestic credit to private sector and GDP in 1980 and is taken from the World Bank Global Development Finance database; from the Barro and Lee (2001) dataset we extract different measures of schooling at the country level such as years of schooling in the population with more than 25 years in 1980, while we compute the capital to output ratio by applying a standard perpetual inventory method to derive the capital stock (and therefore the capital output ratio) for 1980 using data from the most recent release of the Penn World Tables.
